Appendix A: Driver terminology ........................................ 77
This is the manual for Neo4j JavaScript Driver version 4.4, authored by the Neo4j Team.

This manual covers the following areas:

- **Get started** — An overview of the official Neo4j JavaScript Driver and how to connect to a Neo4j database.
- **Client applications** — How to manage database connections within an application.
- **Cypher workflow** — How to create units of work and provide a logical context for that work.
- **The session API** — How the types and values used by Cypher map to native language types.
- **Driver terminology** — Terminology for drivers.

Who should read this?

This manual is written for JavaScript developers building a Neo4j client application.

Building Neo4j Applications with Node.js

In this free course, follow a walk through the steps to integrate Neo4j into your Node.js projects. You will learn about the Neo4j Node.js Driver, how sessions and transactions work and how to query Neo4j from an existing application.

Learn more
Get started

This section gives an overview of the official Neo4j JavaScript Driver and how to connect to a Neo4j database with a "Hello World" example.

About the official JavaScript driver

Neo4j provides official drivers for a number of popular programming languages. These drivers are supported by Neo4j.

Community drivers also exist for many languages, but vary greatly in terms of feature sets, maturity, and support. To find more about community drivers, visit https://neo4j.com/developer/language-guides/.

The following languages and frameworks are officially supported by Neo4j:

Table 1. Supported languages and frameworks for the 4.x driver series

<table>
<thead>
<tr>
<th>Language/framework</th>
<th>Versions supported</th>
</tr>
</thead>
<tbody>
<tr>
<td>.NET</td>
<td>.NET Standard 2.0</td>
</tr>
<tr>
<td>Go</td>
<td>All the Go versions officially supported (<a href="https://go.dev/doc/devel/release#policy">https://go.dev/doc/devel/release#policy</a>)</td>
</tr>
<tr>

<td>Java 8+ (latest patch releases).</td>
</tr>
<tr>
<td>JavaScript</td>
<td>All LTS versions of Node.JS, specifically the 4.x and 6.x series runtimes (<a href="https://github.com/nodejs/LTS">https://github.com/nodejs/LTS</a>).</td>
</tr>
<tr>
<td>Python</td>
<td>Python 3.6 and above.</td>
</tr>
</tbody>
</table>

The driver API is intended to be topologically agnostic. This means that the underlying database topology — single instance, Causal Cluster, etc. — can be altered without requiring a corresponding alteration to application code.

In the general case, only the connection URI needs to be modified when changes are made to the topology.

The official drivers do not support HTTP communication. If you need an HTTP driver, choose one of the community drivers.

See also the HTTP API documentation.
Driver versions and installation

Starting with Neo4j 4.0, the versioning scheme for the database, driver and protocol have all been aligned. This simplifies general compatibility concerns.

Cross-version compatibility is still available, and minimum support for current and previous versions between both server and driver is guaranteed. More specifically, this means that Neo4j 4.0 is guaranteed to be compatible with both 4.0 Drivers and 1.7 Drivers, and the 4.0 Drivers are guaranteed to be compatible with both Neo4j 4.0 and Neo4j 3.5. In cases where at least one peer is below version 4.0, communication will occur in fallback mode, limiting functionality to that available in the lowest-versioned component.

Drivers 1.7 do not support multiple databases and Neo4j Fabric, features introduced in Neo4j 4.0. To be able to run multiple databases online concurrently and to do distributed queries over them, you must upgrade Drivers from 1.7 to 4.0. For information, see 4.0 Migration Guide → Chapter 6. Upgrade Neo4j drivers.

Wherever possible, it is recommended to use the latest stable driver release available. This will provide the greatest degree of stability and will ensure that the full set of server functionality is available. The drivers, when used with Neo4j Enterprise Edition, come with full cluster routing support. The drivers make no explicit distinction between Enterprise Edition and Community Edition however, and simply operate with the functionality made available by Neo4j itself.
Example 2. Acquire the driver

To use the JavaScript driver, it is recommended employing `npm`. To find the latest version of the driver, use:

```
npm show neo4j-driver@* version
```

**Dependencies**

- Babel/Runtime (^7.5.5)
- RxJS (^6.5.2)
- buffer (^6.0.3)
- string_decoder (^1.3.0)

The JavaScript Reactive API is built and exposed via RxJs. A dependency of RxJs is automatically installed with the driver.

Example 1. Installation via npm

To install the latest version of the driver:

```
npm install neo4j-driver
```

It is also an option to install a certain version of the driver.

```
npm install neo4j-driver@$JAVASCRIPT-DRIVER-VERSION
```

In the following example, driver version 4.4 is installed.

```
npm install neo4j-driver@4.4
```

The release notes for this driver are available [here](#).

A "Hello World" example

The example below shows the minimal configuration necessary to interact with Neo4j through the JavaScript driver.
Example 3. Hello World

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password))
const session = driver.session()

try {
  const result = await session.writeTransaction(tx =>
    tx.run(
      'CREATE (a:Greeting) SET a.message = $message RETURN a.message + ", from node "+ id(a)',
      { message: 'hello, world' }
    )
  )

  const singleRecord = result.records[0]
  const greeting = singleRecord.get(0)

  console.log(greeting)
}
finally {
  await session.close()
} // on application exit:
await driver.close()
```

Driver API docs

For a comprehensive listing of all driver functionality, please see the JavaScript API reference documentation.
Client applications

This section describes how to manage database connections within an application.

The Driver Object

Neo4j client applications require a Driver Object which, from a data access perspective, forms the backbone of the application. It is through this object that all Neo4j interaction is carried out, and it should therefore be made available to all parts of the application that require data access.

In languages where thread safety is an issue, the Driver Object can be considered thread-safe.

A note on lifecycle

Applications will typically construct a Driver Object on startup and destroy it on exit.

Destroying a Driver Object will immediately shut down any connections previously opened via that Driver Object, by closing the associated connection pool.

This will have the consequence of rolling back any open transactions, and closing any unconsumed results.

To construct a driver instance, a connection URI and authentication information must be supplied.

Additional configuration details can be supplied if required. The configuration details are immutable for the lifetime of the Driver Object. Therefore, if multiple configurations are required (such as when working with multiple database users) then multiple Driver Objects must be used.

Example 4. The driver lifecycle

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password))

try {
    await driver.verifyConnectivity()
    console.log('Driver created')
} catch (error) {
    console.log('connectivity verification failed. ' + error)
}

const session = driver.session()

try {
    await session.run('CREATE (i:Item)')
} catch (error) {
    console.log('unable to execute query. ' + error)
} finally {
    await session.close()
}

// ... on application exit:
await driver.close()
```
Connection URIs

A connection URI identifies a graph database and how to connect to it. The encryption and trust settings provide detail on how that connection should be secured.

There are significant changes to security settings between Neo4j 3.x and Neo4j 4.x. Please consider the information in this section before upgrading from a previous version. The Migration Guide is also a good source of information about changes in functionality.

Starting with Neo4j 4.0, client-server communication uses only unencrypted local connections by default. This is a change from previous versions, which switched on encryption by default, but generated a self-signed certificate out of the box.

When a full certificate is installed, and encryption is enabled on the driver, full certificate checks are carried out (refer to Operations Manual → SSL framework). Full certificates provide better overall security than self-signed certificates as they include a complete chain of trust back to a root certificate authority.

Neo4j Aura is a secure hosted service backed by full certificates signed by a root certificate authority.

To connect to Neo4j Aura, driver users must enable encryption and the complete set of certificate checks (the latter of which are enabled by default).

For more information, see Examples below.

</table>

Initial address resolution

The address provided in a neo4j:// URI is used for initial and fallback communication only.

This communication occurs to bootstrap the routing table, through which all subsequent communication is carried out. Fallback occurs when the driver is unable to contact any of the addresses held in the routing table. The initial address is once again reused to bootstrap the system.
Several options are available for providing this initial logical-to-physical host resolution. These include regular DNS, custom middleware such as a load balancer, and the Driver Object resolver function, all of which are described in the following sections.

DNS resolution

DNS resolution is the default, and always-available option. As it is possible to configure DNS to resolve a single host name down to multiple IP addresses, this can be used to expose all core server IP addresses under a single host name.

Figure 1. Initial address resolution over DNS

Custom middleware

Middleware, such as a load balancer, can be used to group the core servers under a single public address.
 Resolver function

Neo4j Drivers also present an address resolution intercept hook called the **resolver function**.

This takes the form of a callback function that accepts a single input address and returns multiple output addresses. The function may hard code the output addresses or may draw them from another configuration source, as required.
The example below shows how to expand a single address into multiple (hard-coded) output addresses:

Example 5. Custom Address Resolver

```javascript
function createDriver(virtualUri, user, password, addresses) {
    return neo4j.driver(virtualUri, neo4j.auth.basic(user, password), {
        resolver: address => addresses
    });
}

function addPerson(name) {
    const driver = createDriver('neo4j://x.acme.com', user, password, [
        'a.acme.com:7575',
        'b.acme.com:7676',
        'c.acme.com:8787'
    ])
    const session = driver.session({ defaultAccessMode: neo4j.WRITE })
    session
        .run('CREATE (n:Person { name: $name })', { name: name })
        .then(() => session.close())
        .then(() => driver.close())
}
```

Routing table

The routing table acts like the glue between the driver connectivity layer and the database surface. This table contains a list of server addresses, grouped as readers and writers, and is refreshed automatically by the driver as required.

The driver does not expose any API to work directly with the routing table, but it can sometimes be useful to explore when troubleshooting a system.

Routing context

A routing context can be included as the query part of a `neo4j://` URI.

Routing contexts are defined by means of server policies and allow customization of the contents of the routing table.

Example 6. Configure a routing driver with routing context

This example will assume that Neo4j has been configured for server policies as described in Neo4j Operations Manual → Load balancing for multi-data center systems. In particular, a server policy called europe has been defined. Additionally, we have a server neo01.graph.example.com to which we wish to direct the driver.

This URI will use the server policy europe:

`neo4j://neo01.graph.example.com?policy=europe`
Server-side configuration to enable routing drivers with routing context

A prerequisite for using a routing driver with routing context is that the Neo4j database is operated on a Causal Cluster with the Multi-data center licensing option enabled. Additionally, the routing contexts must be defined within the cluster as routing policies.

For details on how to configure multi-data center routing policies for a Causal Cluster, please refer to Operations Manual → Causal Clustering.

Exposing a single instance deployment on a remote host using the neo4j URI scheme

If you are using a single instance of Neo4j, deployed on a remote machine whilst using the neo4j URI scheme, you will need to complete additional configuration of the server.

To make the server aware of its deployment environment, you need to configure default_advertised_address with your deployment machine's host name, as visible from the client machine.

Examples

Connection URIs are typically formed according to the following pattern:

```
neo4j://<HOST>:<PORT>[?<ROUTING_CONTEXT>]
```

This targets a routed Neo4j service that may be fulfilled by either a cluster or a single instance. The HOST and PORT values contain a logical hostname and port number targeting the entry point to the Neo4j service (e.g. neo4j://graph.example.com:7687).

In a clustered environment, the URI address will resolve to one of more of the core members; for standalone installations, this will simply point to that server address. The ROUTING_CONTEXT option allows for customization of the routing table and is discussed in more detail in Routing context.

An alternative URI form, using the bolt URI scheme (e.g. bolt://graph.example.com:7687), can be used when a single point-to-point connection is required. This variant is useful for the subset client applications (such as admin tooling) that need to be aware of individual servers, as opposed to those which require a highly available database service.

```
bolt://<HOST>:<PORT>
```

Each of the neo4j and bolt URI schemes permit variants that contain extra encryption and trust information. The +s variants enable encryption with a full certificate check, and the +ssc variants enable encryption, but with no certificate check. This latter variant is designed specifically for use with self-signed certificates.

Table 3. Available URI schemes

<table>
<thead>
<tr>
<th>URI scheme</th>
<th>Routing</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>neo4j</td>
<td>Yes</td>
<td>Unsecured</td>
</tr>
<tr>
<td>URI scheme</td>
<td>Routing</td>
<td>Description</td>
</tr>
<tr>
<td>------------</td>
<td>---------</td>
<td>------------------------------------</td>
</tr>
<tr>
<td>neo4j+s</td>
<td>Yes</td>
<td>Secured with full certificate</td>
</tr>
<tr>
<td>neo4j+ssc</td>
<td>Yes</td>
<td>Secured with self-signed certificate</td>
</tr>
<tr>
<td>bolt</td>
<td>No</td>
<td>Unsecured</td>
</tr>
<tr>
<td>bolt+s</td>
<td>No</td>
<td>Secured with full certificate</td>
</tr>
<tr>
<td>bolt+ssc</td>
<td>No</td>
<td>Secured with self-signed certificate</td>
</tr>
</tbody>
</table>

Neo4j 3.x did not provide a routing table in single instance mode and therefore you should use a `bolt://` URI if targeting an older, non-clustered server.

The table below provides example code snippets for different deployment configurations. Each snippet expects an `auth` variable to have been previously defined, containing the authentication details for that connection.

Connecting to a service
The tables below illustrate examples of how to connect to a service with routing:

Table 4. Neo4j Aura, secured with full certificate

<table>
<thead>
<tr>
<th>Product</th>
<th>Neo4j Aura</th>
</tr>
</thead>
<tbody>
<tr>
<td>Security</td>
<td>Secured with full certificate</td>
</tr>
<tr>
<td>Code snippet</td>
<td><code>neo4j.driver(&quot;neo4j+s://graph.example.com:7687&quot;, auth)</code></td>
</tr>
</tbody>
</table>

If you do not have at least the JavaScript Driver 4.0.2 patch installed, you will need this snippet instead:

```javascript
const uri = 'neo4j://graph.example.com:7687'
const driver = neo4j.driver(uri, auth, {
    encrypted: 'ENCRYPTION_ON'
})
```

Comments
This is the default (and only option) for Neo4j Aura.

Table 5. Neo4j 4.x, unsecured
<table>
<thead>
<tr>
<th>Product</th>
<th>Neo4j 4.x</th>
</tr>
</thead>
<tbody>
<tr>
<td>Security</td>

</tbody>
</table>

To connect to a service without routing, you can replace `neo4j` with `bolt`. 
Authentication

Authentication details are provided as an auth token which contains the user names, passwords or other credentials required to access the database. Neo4j supports multiple authentication standards but uses basic authentication by default.

Basic authentication

The basic authentication scheme is backed by a password file stored within the server and requires applications to provide a user name and password. For this, use the basic auth helper:

Example 7. Basic authentication

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password))
```

The basic authentication scheme can also be used to authenticate against an LDAP server.

Kerberos authentication

The Kerberos authentication scheme provides a simple way to create a Kerberos authentication token with a base64 encoded server authentication ticket. The best way to create a Kerberos authentication token is shown below:

Example 8. Kerberos authentication

```javascript
const driver = neo4j.driver(uri, neo4j.auth.kerberos(ticket))
```

The Kerberos authentication token can only be understood by the server if the server has the Kerberos Add-on installed.

Bearer authentication

The bearer scheme allows you to create a bearer authentication token using a base64 encoded bearer authentication token provided by an Identity Provider. This scheme is used in conjunction with Neo4j’s Single Sign-On feature.

The bearer scheme requires configuring Single Sign-On on the server. See the Operations Manual for information on how to configure it. Once configured, clients can discover Neo4j’s configuration through the Discovery API.

The best way to create a bearer authentication token is shown below:
Example 9. Import bearer authentication

```javascript
const driver = neo4j.driver(uri, neo4j.auth.bearer(token))
```

Custom authentication

For advanced deployments, where a custom security provider has been built, the custom authentication helper can be used.

Example 10. Custom authentication

```javascript
const driver = neo4j.driver(
    uri,
    neo4j.auth.custom(principal, credentials, realm, scheme, parameters)
)
```

Configuration

**ConnectionAcquisitionTimeout**

The maximum amount of time a session will wait when requesting a connection from the connection pool. For connection pools where all connections are currently being used and the `MaxConnectionPoolSize` limit has been reached, a session will wait this duration for a connection to be made available. Since the process of acquiring a connection may involve creating a new connection, ensure that the value of this configuration is higher than the configured `ConnectionTimeout`.

Setting a low value will allow for transactions to fail fast when all connections in the pool have been acquired by other transactions. Setting a higher value will result in these transactions being queued, increasing the chances of eventually acquiring a connection at the cost of longer time to receive feedback on failure. Finding an optimal value may require an element of experimentation, taking into consideration the expected levels of parallelism within your application as well as the `MaxConnectionPoolSize`.

**Default:** 60 seconds

Example 11. Configure connection pool

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password), {
    maxConnectionLifetime: 3 * 60 * 60 * 1000, // 3 hours
    maxConnectionPoolSize: 50,
    connectionAcquisitionTimeout: 2 * 60 * 1000 // 120 seconds
})
```

**ConnectionTimeout**

The maximum amount of time to wait for a TCP connection to be established. Connections are only created when a session requires one unless there is an available connection in the connection pool. The driver maintains a pool of open connections which can be loaned to a session when one is available. If a
connection is not available, then an attempt to create a new connection (provided the MaxConnectionPoolSize limit has not been reached) is made with this configuration option, providing the maximum amount of time to wait for the connection to be established.

In environments with high latency and high occurrences of connection timeouts it is recommended to configure a higher value. For lower latency environments and quicker feedback on potential network issues configure with a lower value.

Default: 30 seconds

Example 12. Configure connection timeout

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password), {
  connectionTimeout: 20 * 1000 // 20 seconds
});
```

CustomResolver

Specify a custom server address resolver used by the routing driver to resolve the initial address used to create the driver. See Resolver function for more details.

Encryption

Specify whether to use an encrypted connection between the driver and server.

Default: None

Example 13. Unencrypted configuration

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password), {
  encrypted: 'ENCRYPTION_OFF'
});
```

MaxConnectionLifetime

The maximum duration the driver will keep a connection for before being removed from the pool. Note that while the driver will respect this value, it is possible that the network environment will close connections inside this lifetime. This is beyond the control of the driver. The check on the connection’s lifetime happens when a session requires a connection. If the available connection’s lifetime is over this limit it is closed and a new connection is created, added to the pool and returned to the requesting session. Changing this configuration value would be useful in environments where users don’t have full control over the network environment and wish to proactively ensure all connections are ready.

Setting this option to a low value will cause a high connection churn rate, and can result in a performance drop. It is recommended to pick a value smaller than the maximum lifetime exposed by the surrounding system infrastructure (such as operating system, router, load balancer, proxy and firewall). Negative values result in lifetime not being checked.

Default: 1 hour (3600 seconds)
MaxConnectionPoolSize

The maximum total number of connections allowed, per host (i.e. cluster nodes), to be managed by the connection pool. In other words, for a direct driver using the bolt:// scheme, this sets the maximum number of connections towards a single database server. For a driver connected to a cluster using the neo4j:// scheme, this sets the maximum amount of connections per cluster member. If a session or transaction tries to acquire a connection at a time when the pool size is at its full capacity, it must wait until a free connection is available in the pool or the request to acquire a new connection times out. The connection acquiring timeout is configured via ConnectionAcquisitionTimeout.

This configuration option allows you to manage the memory and I/O resources being used by the driver and tuning this option is dependent on these factors, in addition to number of cluster members.

Default: 100 connections

MaxTransactionRetryTime

The maximum amount of time that a managed transaction will retry for before failing. Queries that are executed within a managed transaction gain the benefit of being retried when a transient error occurs. When this happens the transaction is retired multiple times up to the MaxTransactionRetryTime.

Configure this option higher in high latency environments or if you are executing many large transactions which could limit the number of times that they are retired and therefore their chance to succeed. Configure lower in low latency environments and where your workload mainly consists of many smaller transactions. Failing transactions faster may highlight the reasons behind the transient errors making it easier to fix underlying issues.

Default: 30 seconds

Example 14. Configure maximum retry time

```javascript
const maxRetryTimeMs = 15 * 1000 // 15 seconds
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password), {
  maxTransactionRetryTime: maxRetryTimeMs
})
```

TrustStrategy

Specify how to determine the authenticity of encryption certificates provided by the Neo4j instance that you are connecting to. There are three choices as to which strategy to use:

- **TRUST_SYSTEM_CA_SIGNED_CERTIFICATES** - Accept any certificate that can be verified against the system store.
- **TRUST_CUSTOM_CA_SIGNED_CERTIFICATES** - Accept any certificate that can be verified against a custom CA.
- **TRUST_ALL_CERTIFICATES** - Accept any certificate provided by the server, regardless of CA chain.

We do not recommend using this setting for production environments.

Default: TRUST_SYSTEM_CA_SIGNED_CERTIFICATES (Note - only when encryption is enabled)
Example 15. Configure trusted certificates

```javascript
const driver = neo4j.driver(uri, neo4j.auth.basic(user, password), {
  encrypted: 'ENCRIPTION_ON',
  trust: 'TRUST_ALL_CERTIFICATES'
});
```

Logging

All official Neo4j Drivers log information to standard logging channels. This can typically be accessed in an ecosystem-specific way.

The code snippet below demonstrates how to redirect log messages to standard output:

```javascript
const loggingConfig = {logging: neo4j.logging.console('debug')};
const driver = neo4j.driver(..., loggingConfig);
```
Cypher workflow

This section describes how to create units of work and provide a logical context for that work.

Overview

The Neo4j Drivers expose a Cypher Channel over which database work can be carried out (see the Cypher Manual for more information on the Cypher Query Language).

Work itself is organized into sessions, transactions and queries, as follows:

![Figure 4. Sessions, queries and transactions](image)

Sessions are always bound to a single transaction context, which is typically an individual database.

Using the bookmark mechanism, sessions also provide a guarantee of correct transaction sequencing, even when transactions occur over multiple cluster members. This effect is known as causal chaining.

Sessions

Sessions are lightweight containers for causally chained sequences of transactions (see Operations Manual → Causal consistency). They essentially provide context for storing transaction sequencing information in the form of bookmarks.

When a transaction begins, the session in which it is contained acquires a connection from the driver connection pool. On commit (or rollback) of the transaction, the session releases that connection again. This means that it is only when a session is carrying out work that it occupies a connection resource. When idle, no such resource is in use.

Due to the sequencing guaranteed by a session, sessions may only host one transaction at a time. For parallel execution, multiple sessions should be used. In languages where thread safety is an issue, sessions should not be considered thread-safe.
Closing a session forces any open transaction to be rolled back, and its associated connection to consequently be released back into the pool.

Sessions are bound to a single transactional context, specified on construction. Neo4j exposes each database inside its own context, thereby prohibiting cross-database transactions (or sessions) by design. Similarly, sessions bound to different databases may not be causally chained by propagating bookmarks between them.

Individual language drivers provide several session classes, each oriented around a particular programming style. Each session class provides a similar set of functionality but offers client applications a choice based on how the application is structured and what frameworks are in use, if any.

The session classes are described in The session API. For more details, please see the API documentation.

Transactions

Transactions are atomic units of work containing one or more Cypher Queries. Transactions may contain read or write work, and will generally be routed to an appropriate server for execution, where they will be carried out in their entirety. In case of a transaction failure, the transaction needs to be retried from the beginning. This is the responsibility of the transaction manager.

The Neo4j Drivers provide transaction management via the transaction function mechanism. This mechanism is exposed through methods on the Session object which accept a function object that can be played multiple times against different servers until it either succeeds or a timeout is reached. This approach is recommended for most client applications.

A convenient short-form alternative is the auto-commit transaction mechanism. This provides a limited form of transaction management for single-query transactions, as a trade-off for a slightly smaller code overhead. This form of transaction is useful for quick scripts and environments where high availability guarantees are not required. It is also the required form of transaction for running PERIODIC COMMIT queries, which are the only type of Cypher Query to manage their own transactions.

A lower-level unmanaged transaction API is also available for advanced use cases. This is useful when an alternative transaction management layer is applied by the client, in which error handling and retries need to be managed in a custom way.

To learn more about how to use unmanaged transactions, see API documentation for the relevant language.

Queries and results

Queries consist of a request to the server to execute a Cypher statement, followed by a response back to the client with the result. Results are transmitted as a stream of records, along with header and footer metadata, and can be incrementally consumed by a client application. With reactive capabilities, the semantics of the record stream can be enhanced by allowing a Cypher result to be paused or cancelled part-way through.

To execute a Cypher Query, the query text is required along with an optional set of named parameters. The text can contain parameter placeholders that are substituted with the corresponding values at
runtime. While it is possible to run non-parameterized Cypher Queries, good programming practice is to use parameters in Cypher Queries whenever possible. This allows for the caching of queries within the Cypher Engine, which is beneficial for performance. Parameter values should adhere to Cypher values.

A result summary is also generally available. This contains additional information relating to the query execution and the result content. For an EXPLAIN or PROFILE query, this is where the query plan is returned. See Cypher Manual → Profiling a query for more information on these queries.

Causal chaining and bookmarks

When working with a Causal Cluster, transactions can be chained, via a session, to ensure causal consistency. This means that for any two transactions, it is guaranteed that the second transaction will begin only after the first has been successfully committed. This is true even if the transactions are carried out on different physical cluster members. For more information on Causal Clusters, please refer to Operations Manual → Clustering.

Internally, causal chaining is carried out by passing bookmarks between transactions. Each bookmark records one or more points in transactional history for a particular database, and can be used to inform cluster members to carry out units of work in a particular sequence. On receipt of a bookmark, the server will block until it has caught up with the relevant transactional point in time.

An initial bookmark is sent from client to server on beginning a new transaction, and a final bookmark is returned on successful completion. Note that this applies to both read and write transactions.

Bookmark propagation is carried out automatically within sessions and does not require any explicit signal or setting from the application. To opt out of this mechanism, for unrelated units of work, applications can use multiple sessions. This avoids the small latency overhead of the causal chain.

Bookmarks can be passed between sessions by extracting the last bookmark from a session and passing this into the construction of another. Multiple bookmarks can also be combined if a transaction has more than one logical predecessor. Note that it is only when chaining across sessions that an application will need to work with bookmarks directly.

Figure 5. Passing bookmarks
// Create a company node
function addCompany(tx, name) {
    return tx.run('CREATE (a:Company {name: $name})', { name: name })
}

// Create a person node
function addPerson(tx, name) {
    return tx.run('CREATE (a:Person {name: $name})', { name: name })
}

// Create an employment relationship to a pre-existing company node.
// This relies on the person first having been created.
function addEmployee(tx, personName, companyName) {
    return tx.run(
        'MATCH (person:Person {name: $personName}) ' +
        'MATCH (company:Company {name: $companyName}) ' +
        'CREATE (person)-[:WORKS_FOR]->(company)',
        { personName: personName, companyName: companyName }
    )
}

// Create a friendship between two people.
function makeFriends(tx, name1, name2) {
    return tx.run(
        'MATCH (a:Person {name: $name1}) ' +
        'MATCH (b:Person {name: $name2}) ' +
        'MERGE (a)-[:KNOWS]->(b)',
        { name1: name1, name2: name2 }
    )
}

// To collect friend relationships
const friends = []

// Match and display all friendships.
function findFriendships(tx) {
    const result = tx.run('MATCH (a)-[:KNOWS]->(b) RETURN a.name, b.name')
    result.subscribe({
        onNext: record => {
            const name1 = record.get(0)
            const name2 = record.get(1)
            friends.push({ name1: name1, name2: name2 })
        }
    })
}

// To collect the session bookmarks
const savedBookmarks = []

// Create the first person and employment relationship.
const session1 = driver.session({ defaultAccessMode: neo4j.WRITE })
const first = session1.writeTransaction(tx => addCompany(tx, 'Wayne Enterprises'))
.session() => session1.writeTransaction(tx => addPerson(tx, 'Alice'))
.session() =>
    session1.writeTransaction(tx =>
        addEmployee(tx, 'Alice', 'Wayne Enterprises'))
.then() => {
    savedBookmarks.push(session1.lastBookmark())
})
.then() => session1.close()

// Create the second person and employment relationship.
const session2 = driver.session({ defaultAccessMode: neo4j.WRITE })
const second = session2.writeTransaction(tx => addCompany(tx, 'LexCorp'))
.session() => session2.writeTransaction(tx => addPerson(tx, 'Bob'))
.session() =>
    session2.writeTransaction(tx => addEmployee(tx, 'Bob', 'LexCorp'))
Routing transactions using access modes

Transactions can be executed in either read or write mode; this is known as the access mode. In a Causal Cluster, each transaction will be routed to an appropriate server based on the mode. When using a single instance, all transactions will be passed to that one server.

Routing Cypher by identifying reads and writes can improve the utilization of available cluster resources. Since read servers are typically more plentiful than write servers, it is beneficial to direct read traffic to read servers instead of the write server. Doing so helps in keeping write servers available for write transactions.

Access mode is generally specified by the method used to call the transaction function. Session classes provide a method for calling reads and another for writes.

As a fallback for auto-commit and unmanaged transactions, a default access mode can also be provided at session level. This is only used in cases when the access mode cannot otherwise be specified. In case a transaction function is used within that session, the default access mode will be overridden.

The driver does not parse Cypher and therefore cannot automatically determine whether a transaction is intended to carry out read or write operations. As a result, a write transaction tagged as a read will still be sent to a read server, but will fail on execution.
Example 17. Read-write transaction

```javascript
const session = driver.session()

try {
    await session.writeTransaction(tx =>
    tx.run('CREATE (a:Person {name: $name})', { name: personName })
)

    const result = await session.readTransaction(tx =>
    tx.run('MATCH (a:Person {name: $name}) RETURN id(a)', {
        name: personName
    })
)

    const singleRecord = result.records[0]
    const createdNodeId = singleRecord.get(0)

    console.log('Matched created node with id: ' + createdNodeId)
}
finally {
    await session.close()
}
```

Databases and execution context

Neo4j offers the ability to work with **multiple databases** within the same DBMS.

For **Community Edition**, this is limited to **one user database**, plus the **system** database.

From a driver API perspective, sessions have a DBMS scope, and the default database for a session can be selected on session construction. The default database is used as a target for queries that don’t explicitly specify a database with a **USE** clause. See **Cypher Manual → USE** for details about the **USE** clause.

In a multi-database environment, the server tags one database as **default**. This is selected whenever a session is created without naming a particular database as default. In an environment with a single database, that database is always the default.

For more information about managing multiple databases within the same DBMS, refer to **Cypher Manual → Neo4j databases and graphs**, which has a full breakdown of the Neo4j data storage hierarchy.

The following example illustrates how to work with databases:

```javascript
var session = driver.session(SessionConfig.forDatabase( "foo" ))
// lists nodes from database foo
session.run("MATCH (n) RETURN n").list()

// lists nodes from database bar
session.run("USE bar MATCH (n) RETURN n").list()

// creates an index in foo
session.run("CREATE INDEX foo_idx FOR (n:Person) ON n.id").consume()

// creates an index in bar
session.run("USE bar CREATE INDEX bar_idx FOR (n:Person) ON n.id").consume()

// targets System database
session.run("SHOW USERS")
```
Database selection

You pass the name of the database to the driver during session creation. If you don’t specify a name, the default database is used. The database name must not be `null`, nor an empty string.

The selection of database is only possible when the driver is connected against Neo4j Enterprise Edition. Changing to any other database than the default database in Neo4j Community Edition will lead to a runtime error.

The following example illustrates the concept of DBMS Cypher Manual Transactions and shows how queries to multiple databases can be issued in one driver transaction. It is annotated with comments describing how each operation impacts database transactions.

```java
var session = driver.session(SessionConfig.forDatabase( "foo" ))
// a DBMS-level transaction is started
var transaction = session.begin()
// a transaction on database "foo" is started automatically with the first query targeting foo
transaction.run("MATCH (n) RETURN n").list()
// a transaction on database "bar" is started
transaction.run("USE bar MATCH (n) RETURN n").list()
// executes in the transaction on database "foo"
transaction.run("RETURN 1").consume()
// executes in the transaction on database "bar"
transaction.run("USE bar RETURN 1").consume()
// commits the DBMS-level transaction which commits the transactions on databases "foo" and "bar"
transaction.commit()
```

Please note that the database that is requested must exist.
Example 18. Database selection on session creation

```javascript
const session = driver.session({
  database: 'examples'
})
try {
  const result = await session.writeTransaction(tx =>
    tx.run('CREATE (a:Greeting {message: "Hello, Example-Database"}) RETURN a.message'
  )
)

  const singleRecord = result.records[0]
  const greeting = singleRecord.get(0)

  console.log(greeting)
} finally {
  await session.close()
}

const readSession = driver.session({
  database: 'examples',
  defaultAccessMode: neo4j.READ
})
try {
  const result = await readSession.writeTransaction(tx =>
    tx.run('MATCH (a:Greeting) RETURN a.message'
  )
)

  const singleRecord = result.records[0]
  const greeting = singleRecord.get(0)

  console.log(greeting)
} finally {
  await readSession.close()
}
```

Type mapping

Drivers translate between application language types and the Cypher Types.

To pass parameters and process results, it is important to know the basics of how Cypher works with types and to understand how the Cypher Types are mapped in the driver.

The table below shows the available data types. All types can be potentially found in the result, although not all types can be used as parameters.
<table>
<thead>
<tr>
<th>Cypher Type</th>
<th>Parameter</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>null*</td>
<td></td>
<td>✔</td>
</tr>
<tr>
<td>List</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Map</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Boolean</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Integer</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Float</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>String</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>ByteArray</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Date</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Time</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>LocalTime</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>DateTime</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>LocalDateTime</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Duration</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Point</td>
<td>✔</td>
<td>✔</td>
</tr>
<tr>
<td>Node**</td>
<td></td>
<td>✔</td>
</tr>
<tr>
<td>Relationship**</td>
<td></td>
<td>✔</td>
</tr>
<tr>
<td>Path**</td>
<td></td>
<td>✔</td>
</tr>
</tbody>
</table>

* The null marker is not a type but a placeholder for absence of value. For information on how to work with null in Cypher, please refer to [Cypher Manual → Working with null](#).

** Nodes, relationships and paths are passed in results as snapshots of the original graph entities. While the original entity IDs are included in these snapshots, no permanent link is retained back to the underlying server-side entities, which may be deleted or otherwise altered independently of the client copies. Graph structures may not be used as parameters because it depends on application context whether such a parameter would be passed by reference or by value, and Cypher provides no mechanism to denote this. Equivalent functionality is available by simply passing either the ID for pass-by-reference, or an extracted map of properties for pass-by-value.

The Neo4j Drivers map Cypher Types to and from native language types as depicted in the table below. Custom types (those not available in the language or standard library) are highlighted in **bold**.
### Example 19. Map Neo4j types to JavaScript types

<table>
<thead>
<tr>
<th>Neo4j Cypher Type</th>
<th>JavaScript Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>null</td>
<td>null</td>
</tr>
<tr>
<td>List</td>
<td>Array</td>
</tr>
<tr>
<td>Map</td>
<td>Object</td>
</tr>
<tr>
<td>Boolean</td>

<tr>
<td>Point</td>
<td>Point</td>
</tr>
<tr>
<td>Node</td>
<td>Node</td>
</tr>
<tr>
<td>Relationship</td>
<td>Relationship</td>
</tr>
<tr>
<td>Path</td>
<td>Path</td>
</tr>
</tbody>
</table>

*JavaScript has no native integer type so a custom type is provided. For convenience, this can be disabled through configuration so that the native Number type is used instead. Note that this can lead to a loss of precision.*
Temporal Types

This section lists some basic usage of the temporal types provided by the JavaScript Driver.

dateTime

Represents an instant capturing the date, the time, and the timezone identifier.

```javascript
// Creating DateTime from standard javascript Date.
// Alternatively, the DateTime could be created with
// new neo4j.types.DateTime(year, month, day, hour, minute, second, nanosecond, timeZoneOffsetSeconds)
const dateTime = neo4j.types.DateTime.fromStandardDate(
  standardDate,
  200 // nanosecond (optional)
)

// Getting DateTime field from record
const fieldDateTime = record.get('fieldName')

// Verifying if object is a DateTime
neo4j.isDateTime(fieldDateTime) // true

// Serializing as ISO String
fieldDateTime.toString() // '2021-06-07T13:33:48.788000200+02:00'
```

date

Represents an instant capturing the date, but not the time, nor the timezone.

```javascript
// Creating Date from standard javascript Date.
// Alternatively, the Date could be created with
// new neo4j.types.Date(year, month, day)
const date = neo4j.types.Date.fromStandardDate(standardDate)

// Getting Date field from record
const fieldDate = record.get('fieldName')

// Verifying if object is a Date
neo4j.isDate(fieldDate) // true

// Serializing as ISO String
fieldDate.toString() // '2021-06-07'
```

time

Represents an instant capturing the time of day, and the timezone offset in seconds, but not the date.

```javascript
// Creating Time from standard javascript Date.
// Alternatively, the Time could be created with
// new neo4j.types.Time(hour, minute, second, nanosecond, timeZoneOffsetSeconds)
const time = neo4j.types.Time.fromStandardDate(standardDate,
  200 // nanosecond (optional)
)

// Getting Time field from record
const fieldTime = record.get('fieldName')

// Verifying if object is a Time
neo4j.isTime(fieldTime) // true

// Serializing as ISO String
fieldTime.toString() // '13:39:08.529000200+02:00'
```
**localDateTime**

Represents an instant capturing the date and the time, but not the timezone.

```javascript
// Creating LocalDateTime from standard javascript Date.
// Alternatively, the LocalDateTime could be created with
// new neo4j.types.LocalDateTime(year, month, day, hour, minute, second, nanosecond)
const localDateTime = neo4j.types.LocalDateTime.fromStandardDate(
  standardDate,
  200 // nanosecond (optional)
)

// Getting LocalDateTime field from record
const fieldLocalDateTime = record.get('fieldName')
// Verifying if object is a LocalDateTime
neo4j.isLocalDateTime(fieldLocalDateTime) // true
// Serializing as ISO String
fieldLocalDateTime.toString() // 2021-06-07T13:35:46.344000200
```

**localTime**

Represents an instant capturing the time of day, but not the date, nor the timezone.

```javascript
// Creating LocalTime from standard javascript Date.
// Alternatively, the LocalTime could be created with
// new neo4j.types.LocalTime(hour, minute, second, nanosecond)
const localTime = neo4j.types.LocalTime.fromStandardDate(
  standardDate,
  200 // nanosecond (optional)
)

// Getting LocalTime field from record
const fieldLocalTime = record.get('fieldName')
// Verifying if object is a LocalTime
neo4j.isLocalTime(fieldLocalTime) // true
// Serializing as ISO String
fieldLocalTime.toString() // 13:40:38.539000200
```

**duration**

Represents an ISO 8601 duration. Contains both date-based values (years, months, days) and time-based values (seconds, nanoseconds).

```javascript
// Creating the Duration object
const duration = new neo4j.types.Duration(
  3, // month
  5, // days
  7, // seconds
  11 // nano seconds
)

// Getting Duration field from record
const durationField = record.get('fieldName')
// Verifying if object is a Duration
neo4j.isDuration(durationField) // true
// Serializing as ISO String
durationField.toString() // P3M5DT7.000000011S
```
Geospatial Types

This section lists some basic usage of the geospatial types provided by the Javascript Driver.

**Point**

Represents 2 or 3 dimensional point in Cartesian space or in the WGS84 space. The field SRID indicates the type of the coordinate.

The following table lists the possible values for SRID:

<table>
<thead>
<tr>
<th>SRID</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>7203</td>
<td>2D point in the cartesian space.</td>
</tr>
<tr>
<td>9157</td>
<td>3D point in the cartesian space.</td>
</tr>
<tr>
<td>4326</td>
<td>2D point in the WGS84 space.</td>
</tr>
<tr>
<td>4979</td>
<td>3D point in the WGS84 space.</td>
</tr>
</tbody>
</table>

Examples of Cartesian points instantiation and reading:
Creating a 2D point in Cartesian space

```javascript
const point2d = new neo4j.types.Point( 7203, // SRID 1, // x 5.1 // y );
```

Or in 3D

```javascript
const point3d = new neo4j.types.Point( 9157, // SRID 1, // x -2, // y 3.1 // z );
```

Reading a 2D point from a record

```javascript
const fieldPoint2d = recordWith2dPoint.get('fieldName')
```

Serializing

```javascript
fieldPoint2d.toString() // Point{srId=7203, x=1.0, y=5.1}
```

Accessing fields

```javascript
console.log(  `Point with x=${fieldPoint2d.x}, y=${fieldPoint2d.y}, srId=${fieldPoint2d.srid}` );
```

Verifying if object is a Point

```javascript
neo4j.isPoint(fieldPoint2d) // true
```

Reading a 3D point from a record

```javascript
const fieldPoint3d = recordWith3dPoint.get('fieldName')
```

Serializing

```javascript
fieldPoint3d.toString() // Point{srId=9157, x=1.0, y=-2.0, z=3.1}
```

Accessing fields

```javascript
console.log(  `Point with x=${fieldPoint3d.x}, y=${fieldPoint3d.y}, z=${fieldPoint3d.z}, srId=${fieldPoint3d.srid}` );
```

Verifying if object is a Point

```javascript
neo4j.isPoint(fieldPoint3d) // true
```

Examples of WSG84 points instantiation and reading:
// Creating a 2D point in WGS84 space
const point2d = new neo4j.types.Point(4326, // SRID
1, // x
5.1 // y)

// Or in 3D
const point3d = new neo4j.types.Point(4979, // SRID
1, // x
-2, // y
3.1 // z)

// Reading a 2D point from a record
const fieldPoint2d = recordWith2dPoint.get('fieldName')

// Serializing
fieldPoint2d.toString() // Point{srid=4326, x=1.0, y=5.1}

// Accessing fields
console.log(`Point with x=${fieldPoint2d.x}, y=${fieldPoint2d.y}, srid=${fieldPoint2d.srid}`)

// Verifying if object is a Point
neo4j.isPoint(fieldPoint2d) // true

// Reading a 3D point from a record
const fieldPoint3d = recordWith3dPoint.get('fieldName')

// Serializing
fieldPoint3d.toString() // Point{srid=4979, x=1.0, y=-2.0, z=3.1}

// Accessing fields
console.log(`Point with x=${fieldPoint3d.x}, y=${fieldPoint3d.y}, z=${fieldPoint3d.z}, srid=${fieldPoint3d.srid}`)

// Verifying if object is a Point
neo4j.isPoint(fieldPoint3d) // true

---

Exceptions and error handling

When executing Cypher or carrying out other operations with the driver, certain exceptions and error cases may arise. Server-generated exceptions are each associated with a status code that describes the nature of the problem and a message that provides more detail.

The classifications are listed in the table below.

Table 11. Server status code classifications

<table>
<thead>
<tr>
<th>Classification</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ClientError</td>
<td>The client application has caused an error. The application should amend and retry the operation.</td>
</tr>
<tr>
<td>DatabaseError</td>
<td>The server has caused an error. Retrying the operation will generally be unsuccessful.</td>
</tr>
<tr>
<td>TransientError</td>
<td>A temporary error has occurred. The application should retry the operation.</td>
</tr>
</tbody>
</table>
Service unavailable

A Service Unavailable exception will be signalled when the driver is no longer able to establish communication with the server, even after retries.

Encountering this condition usually indicates a fundamental networking or database problem.

While certain mitigations can be made by the driver to avoid this issue, there will always be cases when this is impossible. As such, it is highly recommended to ensure client applications contain a code path that can be followed when the client is no longer able to communicate with the server.

Transient errors

Transient errors are those which are generated by the server and marked as safe to retry without alteration to the original request. Examples of such errors are deadlocks and memory issues.

When using transaction functions, the driver will usually be able to automatically retry when a transient failure occurs.
The session API

This section details the Session API that is made available by the driver.

The JavaScript Driver supports asynchronous and reactive sessions.

Asynchronous sessions

Asynchronous sessions provide an API wherein function calls typically return available objects such as futures. This allows client applications to work within asynchronous frameworks and take advantage of cooperative multitasking.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor.

See Session configuration for more details.

Transaction functions

Transaction functions are the recommended form for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

| Notice | When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session. |
const session = driver.session()
const titles = []
try {
    const result = await session.readTransaction(tx =>
        tx.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
    )
    const records = result.records
    for (let i = 0; i < records.length; i++) {
        const title = records[i].get(0)
        titles.push(title)
    }
} finally {
    await session.close()
}

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

Unlike other kinds of Cypher Query, PERIODIC COMMIT and CALL {} IN TRANSACTIONS queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → PERIODIC COMMIT query hint
- Cypher Manual → CALL {} IN TRANSACTIONS
async function readProductTitles () {
  const session = driver.session()
  try {
    const result = await session.run(
      `MATCH (p:Product) WHERE p.id = $id RETURN p.title`,
      { id: 0 }
    )
    const records = result.records
    const titles = []
    for (let i = 0; i < records.length; i++) {
      const title = records[i].get(0)
      titles.push(title)
    }
    return titles
  } finally {
    await session.close()
  }
}

Combining Transactions
The driver provides a language idiomatic way to combine multiple transactions within a single asynchronous session.

const session = driver.session()
try {
  const names = await session.readTransaction(async tx => {
    const result = await tx.run(`MATCH (a:Person) RETURN a.name AS name`
      result.records.map(record => record.get('name'))
  })
  const relationshipsCreated = await session.writeTransaction(tx => {
    Promise.all(
      names.map(name =>
        tx.run(`
          MATCH (emp:Person {name: $person_name}) 
          MERGE (com:Company {name: $company_name}) 
          MERGE (emp)-[:WORKS_FOR]->(com)
        `, { person_name: name, company_name: companyName }
      ).then(
        result =>
          result.summary.counters.updates().relationshipsCreated
      ).then(relationshipsCreated =>
        neo4j.int(relationshipsCreated).toInt()
      )
    )
    .then(values => values.reduce((a, b) => a + b))
  })
  console.log(`Created ${relationshipsCreated} employees relationship'
} finally {
  await session.close()
}

Consuming results
The asynchronous session API provides language-idiomatic methods to aid integration with asynchronous applications and frameworks.
const session = driver.session()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
const collectedNames = []

result.subscribe({
  onNext: record => {
    const name = record.get(0)
    collectedNames.push(name)
  },
  onCompleted: () => {
    session.close().then(() => {
      console.log('Names: ' + collectedNames.join(', '))
    })
  },
  onError: error => {
    console.log(error)
  }
})

### Reactive Sessions

Starting with [Neo4j 4.0](https://neo4j.com/docs/developer-manual/current/), the reactive processing of queries is supported. This can be achieved through reactive sessions. Reactive sessions allow for dynamic management of the data that is being exchanged between the driver and the server.

Typical of reactive programming, consumers control the rate at which they consume records from queries and the driver in turn manages the rate at which records are requested from the server. Flow control is supported throughout the entire Neo4j stack, meaning that the query engine responds correctly to the flow control signals. This results in far more efficient resource handling and ensures that the receiving side is not forced to buffer arbitrary amounts of data.

For more information about reactive stream, please see the following:

- The Reactive Manifesto
- Reactive Streams for JVM and JavaScript
- Project Reactor reference documentation
- Introduction to Reactive Extensions to .NET

Reactive sessions will typically be used in a client application that is already oriented towards the reactive style; it is expected that a reactive dependency or framework is in place.

Refer to Get started for more information on recommended dependencies.

### Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

### Transaction functions

This form of transaction requires minimal boilerplate code and allows for a clear separation of database
queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.

```javascript
const session = driver.rxSession()
const result = session.readTransaction(tx =>
  tx
    .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
    .records()
    .pipe(
      map(r => r.get(0)),
      materialize(),
      toArray()
    )
)
```

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See **Session configuration** for more details.

### Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.
Unlike other kinds of Cypher Query, **PERIODIC COMMIT** and **CALL () IN TRANSACTIONS** queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → **PERIODIC COMMIT** query hint
- Cypher Manual → **CALL () IN TRANSACTIONS**

```javascript
function readProductTitles () {
    const session = driver.rxSession()
    return session
        .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', {
            id: 0
        })
        .pipe(
            map(r => r.get(0)),
            materialize(),
            toArray()
        )
}
```

**Consuming results**

To consume data from a query in a reactive session, a subscriber is required to handle the results that are being returned by the publisher.

Each transaction corresponds to a data flow which supplies the data from the server. Result processing begins when records are pulled from this flow. Only one subscriber may pull data from a given flow.

```javascript
const session = driver.rxSession()
const result = session
    .run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
    .pipe(
        map(r => r.get(0)),
        materialize(),
        toArray()
    )
```

**Cancellation**

As per the reactive stream specification, a reactive data flow can be cancelled part way through. This prematurely commits or rolls back the transaction and stops the query engine from producing any more records.

**Session configuration**

**Bookmarks**

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in
a different new session.

**Default:** None (Sessions will initially be created without a bookmark)

**Default Access Mode**

A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

**Default:** Write

**Database**

The database with which the session will interact. When working with a database which is not the default (i.e. the `system` database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

+ See *Operations Manual → The default database* for more information on databases.

+ See below and *Cypher Manual → The DBMS IMPERSONATE privileges* for more information on impersonation.

+ **Default:** the default database as configured on the server.

See more about Database selection.

**Fetch Size**

The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server. This `FetchSize` applies to async-sessions whereas reactive sessions can be controlled directly using the request method of the subscription.

**Default:** 1000 records

**Impersonated User**

Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See *Operations Manual → Per-user home databases* for more information on default database per-user.

**Default:** None (Sessions will be created with the logged user)
Transaction configuration

Additional configuration can be provided to transactions which are executed.

Transaction Timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by `dbms.transaction.timeout`. If no value is provided, the default is taken by the server setting (see Operations Manual → Transaction Management).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with `dbms.transaction.timeout`. In 4.2 and later, `dbms.transaction.timeout` also acts as a maximum which the driver cannot override. For example, with a server setting of `dbms.transaction.timeout=10s` the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with `dbms.transaction.timeout`.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { timeout: 10 }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { metadata: { applicationId: '123' } }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```
The session API

This section details the Session API that is made available by the driver.

The JavaScript Driver supports asynchronous and reactive sessions.

Asynchronous sessions

Asynchronous sessions provide an API wherein function calls typically return available objects such as futures. This allows client applications to work within asynchronous frameworks and take advantage of cooperative multitasking.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor.

See Session configuration for more details.

Transaction functions

Transaction functions are the recommended form for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

<tr>
<td>When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.</td>
</tr>
</tbody>
</table>
const session = driver.session()
const titles = []
try {
  const result = await session.readTransaction(tx =>
    tx.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
  )
  const records = result.records
  for (let i = 0; i < records.length; i++) {
    const title = records[i].get(0)
    titles.push(title)
  }
} finally {
  await session.close()
}

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

Unlike other kinds of Cypher Query, PERIODIC COMMIT and CALL {} IN TRANSACTIONS queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → PERIODIC COMMIT query hint
- Cypher Manual → CALL {} IN TRANSACTIONS
async function readProductTitles() {
    const session = driver.session()
    try {
        const result = await session.run(
            'MATCH (p:Product) WHERE p.id = $id RETURN p.title',
            {
                id: 0
            }
        )
        const records = result.records
        const titles = []
        for (let i = 0; i < records.length; i++) {
            const title = records[i].get(0)
            titles.push(title)
        }
        return titles
    } finally {
        await session.close()
    }
}

Combining Transactions

The driver provides a language idiomatic way to combine multiple transactions within a single asynchronous session.

const session = driver.session()
try {
    const names = await session.readTransaction(async tx => {
        const result = await tx.run('MATCH (a:Person) RETURN a.name AS name')
        return result.records.map(record => record.get('name'))
    })
    const relationshipsCreated = await session.writeTransaction(tx =>
        Promise.all(
            names.map(name =>
                tx
                .run(
                    'MATCH (emp:Person {name: $person_name}) ' +
                    'MERGE (com:Company {name: $company_name}) ' +
                    'MERGE (emp)-[:WORKS_FOR]->(com)',
                    { person_name: name, company_name: companyName }
                )
                .then(
                    result =>
                    result.summary.counters.updates().relationshipsCreated
                )
                .then(relationshipsCreated =>
                    neo4j.int(relationshipsCreated).toInt()
                )
                .then(values => values.reduce((a, b) => a + b))
            )
        ).then(console.log('Created ${relationshipsCreated} employees relationship'))
    }) finally {
        await session.close()
    }

Consuming results

The asynchronous session API provides language-idiomatic methods to aid integration with asynchronous applications and frameworks.
const session = driver.session()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
const collectedNames = []

result.subscribe({
onNext: record => {
  const name = record.get(0)
  collectedNames.push(name)
},
onCompleted: () => {
  session.close().then(() => {
    console.log('Names: ' + collectedNames.join(', '))
  })
},
onError: error => {
  console.log(error)
})

Reactive Sessions

Starting with Neo4j 4.0, the reactive processing of queries is supported. This can be achieved through reactive sessions. Reactive sessions allow for dynamic management of the data that is being exchanged between the driver and the server.

Typical of reactive programming, consumers control the rate at which they consume records from queries and the driver in turn manages the rate at which records are requested from the server. Flow control is supported throughout the entire Neo4j stack, meaning that the query engine responds correctly to the flow control signals. This results in far more efficient resource handling and ensures that the receiving side is not forced to buffer arbitrary amounts of data.

For more information about reactive stream, please see the following:

- The Reactive Manifesto
- Reactive Streams for JVM and JavaScript
- Project Reactor reference documentation
- Introduction to Reactive Extensions to .NET

Reactive sessions will typically be used in a client application that is already oriented towards the reactive style; it is expected that a reactive dependency or framework is in place.

Refer to Get started for more information on recommended dependencies.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Transaction functions

This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic.
and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.

```plaintext
const session = driver.rxSession()
const result = session.readTransaction(tx =>
  tx
    .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
    .records()
    .pipe(
      map(r => r.get(0)),
      materialize(),
      toArray()
    )
)
```

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See Session configuration for more details.

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.
Unlike other kinds of Cypher Query, `PERIODIC COMMIT` and `CALL {} IN TRANSACTIONS` queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → `PERIODIC COMMIT` query hint
- Cypher Manual → `CALL {} IN TRANSACTIONS` function

```javascript
function readProductTitles () {
  const session = driver.rxSession()
  return session
    .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', {
      id: 0
    })
    .records()
    .pipe(
      map(r => r.get(0)),
      materialize(),
      toArray()
    )
}
```

Consuming results

To consume data from a query in a reactive session, a subscriber is required to handle the results that are being returned by the publisher.

Each transaction corresponds to a data flow which supplies the data from the server. Result processing begins when records are pulled from this flow. Only one subscriber may pull data from a given flow.

```javascript
const session = driver.rxSession()
const result = session
  .run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
  .records()
  .pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
```

Cancellation

As per the reactive stream specification, a reactive data flow can be cancelled part way through. This prematurely commits or rolls back the transaction and stops the query engine from producing any more records.

Session configuration

Bookmarks

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in a different new session.
Default: None (Sessions will initially be created without a bookmark)

Default Access Mode

A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

Default: Write

Database

The database with which the session will interact. When working with a database which is not the default (i.e. the system database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

+ See Operations Manual → The default database for more information on databases.

+ See below and Cypher Manual → The DBMS IMPERSONATE privileges for more information on impersonation.

+ Default: the default database as configured on the server.

See more about Database selection.

Fetch Size

The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server. This FetchSize applies to async-sessions whereas reactive sessions can be controlled directly using the request method of the subscription.

Default: 1000 records

Impersonated User

Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See Operations Manual → Per-user home databases for more information on default database per-user.

Default: None (Sessions will be created with the logged user)
Transaction configuration

Additional configuration can be provided to transactions which are executed.

Transaction Timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by `dbms.transaction.timeout`. If no value is provided, the default is taken by the server setting (see Operations Manual → Transaction Management).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with `dbms.transaction.timeout`. In 4.2 and later, `dbms.transaction.timeout` also acts as a maximum which the driver cannot override. For example, with a server setting of `dbms.transaction.timeout=10s` the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with `dbms.transaction.timeout`.

```javascript
const session = driver.session()
try {
    const result = await session.writeTransaction(
        tx => addPerson(tx, personName),
        { timeout: 10 }
    )

    const singleRecord = result.records[0]
    const createdNodeId = singleRecord.get(0)

    console.log('Created node with id: ' + createdNodeId)
} finally {
    await session.close()
}
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```javascript
const session = driver.session()
try {
    const result = await session.writeTransaction(
        tx => addPerson(tx, personName),
        { metadata: { applicationId: '123' } }
    )

    const singleRecord = result.records[0]
    const createdNodeId = singleRecord.get(0)

    console.log('Created node with id: ' + createdNodeId)
} finally {
    await session.close()
}
```
The session API

This section details the Session API that is made available by the driver.

The JavaScript Driver supports asynchronous and reactive sessions.

Asynchronous sessions

Asynchronous sessions provide an API wherein function calls typically return available objects such as futures. This allows client applications to work within asynchronous frameworks and take advantage of cooperative multitasking.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor.

See Session configuration for more details.

Transaction functions

Transaction functions are the recommended form for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

| | When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session. |
const session = driver.session()
const titles = []
try {
    const result = await session.readTransaction(tx =>
        tx.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
    )
    const records = result.records
    for (let i = 0; i < records.length; i++) {
        const title = records[i].get(0)
        titles.push(title)
    }
} finally {
    await session.close()
}

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

Unlike other kinds of Cypher Query, PERIODIC COMMIT and CALL {} IN TRANSACTIONS queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → PERIODIC COMMIT query hint
- Cypher Manual → CALL {} IN TRANSACTIONS
async function readProductTitles () {
    const session = driver.session()
    try {
        const result = await session.run(
            'MATCH (p:Product) WHERE p.id = $id RETURN p.title',
            { id: 0 }
        )
        const records = result.records
        const titles = []
        for (let i = 0; i < records.length; i++) {
            const title = records[i].get(0)
            titles.push(title)
        }
        return titles
    } finally {
        await session.close()
    }
}

Combining Transactions

The driver provides a language idiomatic way to combine multiple transactions within a single asynchronous session.

const session = driver.session()
try {
    const names = await session.readTransaction(async tx => {
        const result = await tx.run('MATCH (a:Person) RETURN a.name AS name')
        return result.records.map(record => record.get('name'))
    })

    const relationshipsCreated = await session.writeTransaction(tx =>
        Promise.all(names.map(name =>
            tx.run(
                'MATCH (emp:Person {name: $person_name}) ' +
                'MERGE (com:Company {name: $company_name}) ' +
                'MERGE (emp)-[:WORKS_FOR]->(com)',
                { person_name: name, company_name: companyName }
            ).then(
                result =>
                result.summary.counters.updates().relationshipsCreated
            ).then(relationshipsCreated =>
                neo4j.int(relationshipsCreated).toInt()
            ).then(values => values.reduce((a, b) => a + b))
        )
    ).then(values => values.reduce((a, b) => a + b))
    console.log('Created ${relationshipsCreated} employees relationship')
}
finally {
    await session.close()
}

Consuming results

The asynchronous session API provides language-idiomatic methods to aid integration with asynchronous applications and frameworks.
```javascript
const session = driver.session()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
const collectedNames = []

result.subscribe({
  onNext: record => {
    const name = record.get(0)
    collectedNames.push(name)
  },
  onCompleted: () => {
    session.close().then(() => {
      console.log('Names: ' + collectedNames.join(', '))
    })
  },
  onError: error => {
    console.log(error)
  }
})
```

**Reactive Sessions**

Starting with Neo4j 4.0, the reactive processing of queries is supported. This can be achieved through reactive sessions. Reactive sessions allow for dynamic management of the data that is being exchanged between the driver and the server.

Typical of reactive programming, consumers control the rate at which they consume records from queries and the driver in turn manages the rate at which records are requested from the server. Flow control is supported throughout the entire Neo4j stack, meaning that the query engine responds correctly to the flow control signals. This results in far more efficient resource handling and ensures that the receiving side is not forced to buffer arbitrary amounts of data.

For more information about reactive stream, please see the following:

- The Reactive Manifesto
- Reactive Streams for JVM and JavaScript
- Project Reactor reference documentation
- Introduction to Reactive Extensions to .NET

---

**Lifecycle**

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

**Transaction functions**

This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic.
and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors.

Retry logic can be configured when creating a session.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See Session configuration for more details.

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.
Unlike other kinds of Cypher Query, `PERIODIC COMMIT` and `CALL {} IN TRANSACTIONS` queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → `PERIODIC COMMIT` query hint
- Cypher Manual → `CALL {} IN TRANSACTIONS` function

```javascript
function readProductTitles () {
  const session = driver.rxSession()
  return session
    .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', {
      id: 0
    })
    .records()
    .pipe(
      map(r => r.get(0)),
      materialize(),
      toArray()
    )
}
```

Consuming results

To consume data from a query in a reactive session, a subscriber is required to handle the results that are being returned by the publisher.

Each transaction corresponds to a data flow which supplies the data from the server. Result processing begins when records are pulled from this flow. Only one subscriber may pull data from a given flow.

```javascript
const session = driver.rxSession()
const result = session
  .run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
  .records()
  .pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
```

Cancellation

As per the reactive stream specification, a reactive data flow can be cancelled part way through. This prematurely commits or rolls back the transaction and stops the query engine from producing any more records.

Session configuration

Bookmarks

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in a different new session.
**Default: None** (Sessions will initially be created without a bookmark)

**Default Access Mode**
A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

**Default:** Write

**Database**
The database with which the session will interact. When working with a database which is not the default (i.e. the `system` database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

+ See Operations Manual → The default database for more information on databases.

+ See below and Cypher Manual → The DBMS IMPERSONATE privileges for more information on impersonation.

+ **Default:** the default database as configured on the server.

See more about Database selection.

**Fetch Size**
The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server. This FetchSize applies to async-sessions whereas reactive sessions can be controlled directly using the request method of the subscription.

**Default:** 1000 records

**Impersonated User**
Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See Operations Manual → Per-user home databases for more information on default database per-user.

**Default:** None (Sessions will be created with the logged user)
Transaction configuration

Additional configuration can be provided to transactions which are executed.

Transaction Timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by `dbms.transaction.timeout`. If no value is provided, the default is taken by the server setting (see Operations Manual → Transaction Management).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with `dbms.transaction.timeout`. In 4.2 and later, `dbms.transaction.timeout` also acts as a maximum which the driver cannot override. For example, with a server setting of `dbms.transaction.timeout=10s` the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with `dbms.transaction.timeout`.

```javascript
const session = driver.session()
try {
    const result = await session.writeTransaction(
        tx => addPerson(tx, personName),
        { timeout: 10 }
    )

    const singleRecord = result.records[0]
    const createdNodeId = singleRecord.get(0)

    console.log('Created node with id: ' + createdNodeId)
} finally {
    await session.close()
}
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```javascript
const session = driver.session()
try {
    const result = await session.writeTransaction(
        tx => addPerson(tx, personName),
        { metadata: { applicationId: '123' } }
    )

    const singleRecord = result.records[0]
    const createdNodeId = singleRecord.get(0)

    console.log('Created node with id: ' + createdNodeId)
} finally {
    await session.close()
}
```
The session API

This section details the Session API that is made available by the driver.

The JavaScript Driver supports asynchronous and reactive sessions.

Asynchronous sessions

Asynchronous sessions provide an API wherein function calls typically return available objects such as futures. This allows client applications to work within asynchronous frameworks and take advantage of cooperative multitasking.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor.

See Session configuration for more details.

Transaction functions

Transaction functions are the recommended form for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server.

These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.
const session = driver.session()
const titles = []
try {
    const result = await session.readTransaction(tx =>
        tx.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
    )
    const records = result.records
    for (let i = 0; i < records.length; i++) {
        const title = records[i].get(0)
        titles.push(title)
    }
} finally {
    await session.close()
}

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

Unlike other kinds of Cypher Query, PERIODIC COMMIT and CALL {} IN TRANSACTIONS queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → PERIODIC COMMIT query hint
- Cypher Manual → CALL {} IN TRANSACTIONS
async function readProductTitles () {
    const session = driver.session()
    try {
        const result = await session.run(
            'MATCH (p:Product) WHERE p.id = $id RETURN p.title',
            { id: 0
          }
        )
        const records = result.records
        const titles = []
        for (let i = 0; i < records.length; i++) {
            const title = records[i].get(0)
            titles.push(title)
        }
        return titles
    } finally {
        await session.close()
    }
}

Combining Transactions

The driver provides a language idiomatic way to combine multiple transactions within a single asynchronous session.

const session = driver.session()
try {
    const names = await session.readTransaction(async tx => {
        const result = await tx.run('MATCH (a:Person) RETURN a.name AS name')
        return result.records.map(record => record.get('name'))
    })
    const relationshipsCreated = await session.writeTransaction(tx => {
        Promise.all(
            names.map(name =>
                tx.run(
                    'MATCH (emp:Person {name: $person_name}) ' +
                    'MERGE (com:Company {name: $company_name}) ' +
                    'MERGE (emp)-[:WORKS_FOR]->(com)',
                    { person_name: name, company_name: companyName }
                ).then(
                    result =>
                        result.summary.counters.updates().relationshipsCreated
                ).then(relationshipsCreated =>
                    neo4j.int(relationshipsCreated).toInt()
                )
            ).then(values => values.reduce((a, b) => a + b))
        )
        console.log('Created ${relationshipsCreated} employees relationship')
    }) finally {
        await session.close()
    }
}

Consuming results

The asynchronous session API provides language-idiomatic methods to aid integration with asynchronous applications and frameworks.
const session = driver.session()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
const collectedNames = []

result.subscribe(
  onNext: record => {
    const name = record.get(0)
    collectedNames.push(name)
  },
  onCompleted: () => {
    session.close().then(() => {
      console.log('Names: ' + collectedNames.join(', '))
    })
  },
  onError: error => {
    console.log(error)
  }
)

Reactive Sessions

Starting with Neo4j 4.0, the reactive processing of queries is supported. This can be achieved through reactive sessions. Reactive sessions allow for dynamic management of the data that is being exchanged between the driver and the server.

Typical of reactive programming, consumers control the rate at which they consume records from queries and the driver in turn manages the rate at which records are requested from the server. Flow control is supported throughout the entire Neo4j stack, meaning that the query engine responds correctly to the flow control signals. This results in far more efficient resource handling and ensures that the receiving side is not forced to buffer arbitrary amounts of data.

For more information about reactive stream, please see the following:

- The Reactive Manifesto
- Reactive Streams for JVM and JavaScript
- Project Reactor reference documentation
- Introduction to Reactive Extensions to .NET

Reactive sessions will typically be used in a client application that is already oriented towards the reactive style; it is expected that a reactive dependency or framework is in place.

Refer to Get started for more information on recommended dependencies.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Transaction functions

This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic
and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.

```javascript
const session = driver.rxSession()
const result = session.readTransaction(tx =>
  tx
  .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
  .records()
  .pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
)
```

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See Session configuration for more details.

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.
Unlike other kinds of Cypher Query, **PERIODIC COMMIT** and **CALL {} IN TRANSACTIONS** queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → **PERIODIC COMMIT** query hint
- Cypher Manual → **CALL {} IN TRANSACTIONS** function

```javascript
function readProductTitles () {
  const session = driver.rxSession()
  return session
    .run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', {
      id: 0
    })
    .records()
    .pipe(
      map(r => r.get(0)),
      materialize(),
      toArray()
    )
}
```

**Consuming results**

To consume data from a query in a reactive session, a subscriber is required to handle the results that are being returned by the publisher.

Each transaction corresponds to a data flow which supplies the data from the server. Result processing begins when records are pulled from this flow. Only one subscriber may pull data from a given flow.

```javascript
const session = driver.rxSession()
const result = session
  .run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
  .records()
  .pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
```

**Cancellation**

As per the reactive stream specification, a reactive data flow can be cancelled part way through. This prematurely commits or rolls back the transaction and stops the query engine from producing any more records.

**Session configuration**

**Bookmarks**

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in a different new session.
**Default**: None (Sessions will initially be created without a bookmark)

**Default Access Mode**

A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

**Default**: Write

**Database**

The database with which the session will interact. When working with a database which is not the default (i.e. the `system` database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

+ See [Operations Manual ➔ The default database](#) for more information on databases.

+ See below and [Cypher Manual ➔ The DBMS IMPERSONATE privileges](#) for more information on impersonation.

+ Default: the default database as configured on the server.

See more about [Database selection](#).

**Fetch Size**

The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server. This FetchSize applies to `async-sessions` whereas `reactive sessions` can be controlled directly using the request method of the subscription.

**Default**: 1000 records

**Impersonated User**

Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See [Operations Manual ➔ Per-user home databases](#) for more information on default database per-user.

**Default**: None (Sessions will be created with the logged user)
Transaction configuration

Additional configuration can be provided to transactions which are executed.

Transaction Timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by `dbms.transaction.timeout`. If no value is provided, the default is taken by the server setting (see Operations Manual ➔ Transaction Management).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with `dbms.transaction.timeout`. In 4.2 and later, `dbms.transaction.timeout` also acts as a maximum which the driver cannot override. For example, with a server setting of `dbms.transaction.timeout=10s` the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with `dbms.transaction.timeout`.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { timeout: 10 }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { metadata: { applicationId: '123' } }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```
The session API

This section details the Session API that is made available by the driver.

The JavaScript Driver supports asynchronous and reactive sessions.

Asynchronous sessions

Asynchronous sessions provide an API wherein function calls typically return available objects such as futures. This allows client applications to work within asynchronous frameworks and take advantage of cooperative multitasking.

Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor.

See Session configuration for more details.

Transaction functions

Transaction functions are the recommended form for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server.

These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.
const session = driver.session()
const titles = []
try {
  const result = await session.readTransaction(tx =>
    tx.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', { id: 0 })
  )

  const records = result.records
  for (let i = 0; i < records.length; i++) {
    const title = records[i].get(0)
    titles.push(title)
  }
} finally {
  await session.close()
}

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

⚠️ The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

ℹ️ Unlike other kinds of Cypher Query, PERIODIC COMMIT and CALL {} IN TRANSACTIONS queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → PERIODIC COMMIT query hint
- Cypher Manual → CALL {} IN TRANSACTIONS
async function readProductTitles () {
    const session = driver.session()
    try {
        const result = await session.run(
            'MATCH (p:Product) WHERE p.id = $id RETURN p.title',
            {
                id: 0
            }
        )
        const records = result.records
        const titles = []
        for (let i = 0; i < records.length; i++) {
            const title = records[i].get(0)
            titles.push(title)
        }
        return titles
    } finally {
        await session.close()
    }
}

Combining Transactions

The driver provides a language idiomatic way to combine multiple transactions within a single asynchronous session.

```javascript
const session = driver.session()
try {
    const names = await session.readTransaction(async tx => {
        const result = await tx.run('MATCH (a:Person) RETURN a.name AS name')
        return result.records.map(record => record.get('name'))
    })

    const relationshipsCreated = await session.writeTransaction(tx => {
        Promise.all(names.map(name =>
            tx.run(
                'MATCH (emp:Person {name: $person_name}) ' +
                'MERGE (com:Company {name: $company_name}) ' +
                'MERGE (emp)-[:WORKS_FOR]->(com)',
                { person_name: name, company_name: companyName }
            ).then(
                result => result.summary.counters.updates().relationshipsCreated
            ).then(relationshipsCreated =>
                neo4j.int(relationshipsCreated).toInt()
            ).then(values => values.reduce((a, b) => a + b))
        )
        console.log('Created ${relationshipsCreated} employees relationship')
    }) finally {
        await session.close()
    }
```

Consuming results

The asynchronous session API provides language-idiomatic methods to aid integration with asynchronous applications and frameworks.
const session = driver.session()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
const collectedNames = []

result.subscribe(
  onNext: record => {
    const name = record.get(0)
    collectedNames.push(name)
  },
  onCompleted: () => {
    session.close().then(() => {
      console.log('Names: ' + collectedNames.join(', '))
    })
  },
  onError: error => {
    console.log(error)
  }
)

### Reactive Sessions

Starting with Neo4j 4.0, the reactive processing of queries is supported. This can be achieved through reactive sessions. Reactive sessions allow for dynamic management of the data that is being exchanged between the driver and the server.

Typical of reactive programming, consumers control the rate at which they consume records from queries and the driver in turn manages the rate at which records are requested from the server. Flow control is supported throughout the entire Neo4j stack, meaning that the query engine responds correctly to the flow control signals. This results in far more efficient resource handling and ensures that the receiving side is not forced to buffer arbitrary amounts of data.

For more information about reactive stream, please see the following:

- The Reactive Manifesto
- Reactive Streams for JVM and JavaScript
- Project Reactor reference documentation
- Introduction to Reactive Extensions to .NET

Reactive sessions will typically be used in a client application that is already oriented towards the reactive style; it is expected that a reactive dependency or framework is in place.

Refer to [Get started](#) for more information on recommended dependencies.

### Lifecycle

Session lifetime begins with session construction. A session then exists until it is closed, which is typically set to occur after its contained query results have been consumed.

### Transaction functions

This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic. Transaction functions are also desirable since they encapsulate retry logic
and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are in a single instance environment, this routing has no impact but it does give you the flexibility should you choose to later adopt a clustered environment.

Before writing a transaction function it is important to ensure that any side-effects carried out by a transaction function should be designed to be idempotent. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors. Retry logic can be configured when creating a session.

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See Session configuration for more details.

Auto-commit transactions

An auto-commit transaction is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve two purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a retry or undo under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.
Unlike other kinds of Cypher Query, **PERIODIC COMMIT** and **CALL {} IN TRANSACTIONS** queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- Cypher Manual → **PERIODIC COMMIT** query hint
- Cypher Manual → **CALL {} IN TRANSACTIONS** function

```javascript
function readProductTitles () {
  const session = driver.rxSession()
  return session.run('MATCH (p:Product) WHERE p.id = $id RETURN p.title', {
    id: 0
  }).records().pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
}
```

### Consuming results

To consume data from a query in a reactive session, a subscriber is required to handle the results that are being returned by the publisher.

Each transaction corresponds to a data flow which supplies the data from the server. Result processing begins when records are pulled from this flow. Only one subscriber may pull data from a given flow.

```javascript
const session = driver.rxSession()
const result = session.run('MATCH (a:Person) RETURN a.name ORDER BY a.name')
  .records()
  .pipe(
    map(r => r.get(0)),
    materialize(),
    toArray()
  )
```

### Cancellation

As per the reactive stream specification, a reactive data flow can be cancelled part way through. This prematurely commits or rolls back the transaction and stops the query engine from producing any more records.

### Session configuration

#### Bookmarks

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in a different new session.
Default: None (Sessions will initially be created without a bookmark)

Default Access Mode

A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

Default: Write

Database

The database with which the session will interact. When working with a database which is not the default (i.e. the system database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

+ See Operations Manual → The default database for more information on databases.

+ See below and Cypher Manual → The DBMS IMPERSONATE privileges for more information on impersonation.

+ Default: the default database as configured on the server.

See more about Database selection.

Fetch Size

The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server. This FetchSize applies to async-sessions whereas reactive sessions can be controlled directly using the request method of the subscription.

Default: 1000 records

Impersonated User

Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See Operations Manual → Per-user home databases for more information on default database per-user.

Default: None (Sessions will be created with the logged user)
Transaction configuration

Additional configuration can be provided to transactions which are executed.

Transaction Timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by \texttt{dbms.transaction.timeout}. If no value is provided, the default is taken by the server setting (see Operations Manual \textsection Transaction Management).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with \texttt{dbms.transaction.timeout}. In 4.2 and later, \texttt{dbms.transaction.timeout} also acts as a maximum which the driver cannot override. For example, with a server setting of \texttt{dbms.transaction.timeout=10s} the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with \texttt{dbms.transaction.timeout}.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { timeout: 10 }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```javascript
const session = driver.session()
try {
  const result = await session.writeTransaction(
    tx => addPerson(tx, personName),
    { metadata: { applicationId: '123' } }
  )

  const singleRecord = result.records[0]
  const createdNodeId = singleRecord.get(0)

  console.log('Created node with id: ' + createdNodeId)
} finally {
  await session.close()
}
```
Appendix A: Driver terminology

This section lists the relevant terminology related to Neo4j drivers.

access mode
The mode in which a transaction is executed, either read or write.

acquire (connection)
To borrow a driver connection that is not currently in use from a connection pool.

auto-commit
A single query which is wrapped in a transaction and committed automatically.

Bolt
Bolt is a Neo4j proprietary, binary protocol used for communication between client applications and database servers. Bolt is versioned independently from the database and the drivers.

Bolt Routing Protocol
The steps required for a driver to obtain a routing table from a cluster member.

Bolt server
A Neo4j instance that can accept incoming Bolt connections.

bookmark
A marker for a point in the transactional history of Neo4j.

causal chaining
A mechanism to ensure that the transactions carried out in a session are executed in order, even when each transaction may be carried out on different cluster members.

client application
A piece of software that interacts with a database server via a driver.

connection
A persistent communication channel between a client application and a database server.

connection pool
A set of connections maintained for quick access, that can be acquired and released as required.

driver (object)
A globally accessible controller for all database access.

driver (package)
A software library that provides access to Neo4j from a particular programming language. The Neo4j drivers implement the Bolt protocol.
query result
   The stream of records that are returned on execution of a query.

release (connection)
   To return a connection back into a connection pool after use.

routing driver
   A driver that can route traffic to multiple members of a cluster using the routing protocol.

routing table
   A set of server addresses that identify cluster members associated with roles.

server address
   A combination of host name and port or IP address and port that targets a server.

session
   A causally linked sequence of transactions.

thread safety

transaction
   A transaction comprises a unit of work performed against a database. It is treated in a coherent and reliable way, independent of other transactions. A transaction, by definition, must be atomic, consistent, isolated, and durable.

transaction function
   The method of grouping a number of queries together which, when run in a session, are retried on failure.

transaction manager
   The component/code responsible for deciding what to do if a transaction fails, i.e to retry, give up or do something else.
